Summary

In the last decades cosmological N-body dark matter simulations have enabled ab initio studies of the formation of structure in the Universe. Gravity amplified small density fluctuations generated shortly after the Big Bang, leading to the formation of galaxies in the cosmic web. These calculations have led to a growing demand for methods to analyze time-dependent particle based simulations. Rendering methods for such N-body simulation data usually approximate the spatial distributions of physical quantities using kernel interpolation techniques, common in SPH (smoothed particle hydrodynamics)-codes.

We present a GPU-based rendering approach, based on a new, accurate method to compute the physical densities of dark matter simulation data. It uses full phase-space information to generate a tetrahedral tessellation of the computational domain, with mesh vertices defined by the simulation’s dark matter particle positions. Over time the mesh is deformed by gravitational forces, causing the tetrahedral cells to warp and overlap. The new methods are well suited to visualize the cosmic web. In particular they preserve caustics, regions of high density that emerge, when several streams of dark matter particles share the same location in space, indicating the formation of large-scale structures, like sheets, filaments and halos.

GPU Implementation

The special nature of the initial conditions allows for a very memory efficient representation of the mesh on the GPU, without the need to store and transfer any explicit connectivity information or additional attributes about the tetrahedral cells, except for the positions of the tracer particles. All connectivity and derived information, like the volumes and mass densities of the tetrahedral cells, are generated on-the-fly on the GPU in OpenGL shaders.

The tracer particle positions are stored in a three-dimensional float volume and processed in the geometry shader. Here the six (deformed) tetrahedra are constructed, based on the current tracer positions, and the mass as well as the volume for each tetrahedron is computed on-the-fly. A cell-projection approach in the fragment shader is used to compute the accumulated projected densities in the image plane.

Results

At early times, the dark matter fluid is almost uniformly distributed and at rest, as depicted by the red line in the Figure below. Over time, gravity accelerates the dark matter fluid elements and they gain velocity, denoted by the green line. At later times different streams of dark matter co-exist in the same spatial region, in this example there are three regions per spatial location for elements on the blue line inside the transparent box. These so-called multi-stream regions provide important information about the formation of structures in the dark matter distribution on large spatial scales.

Given a time-dependent 3D N-body dark matter simulation, a tetrahedral mesh is constructed, with a connectivity implicitly defined by the layout of the tracers on a regular grid at the initial time-step, which can be reconstructed at any time step from the tracer’s unique IDs. The same amount of mass is assigned to each tetrahedral element and derived quantities, like time-dependent mass densities, are computed based on the volumes of all tetrahedral elements that overlap a certain location. The mass is associated with the cells and not the vertices of the tessellation. The nodes of the mesh are updated over time, according to the tracer’s actual position, changing the volumes and thus the spatial mass densities. The tessellation has consistent vertices, edges and faces for abutting cells, and in particular does not contain any dangling nodes, but at later times the tetrahedral elements will typically start to overlap.

Application

A density distribution from a dark matter simulation with about 134 million particles, resulting in about 804 million tetrahedra, respectively 3.2 billion triangles. The close-up on the left shows a regular grid with the initial time-step and the right one shows the same volume after 200 time-steps, indicating the formation of large-scale structures like sheets, filaments and halos.

The new visualization method was used to render a full-dome animation for the new space show “Dark Universe”, produced and shown at the Hayden Planetarium (American Museum of Natural History) in New York City. The show features basic cosmological concepts and current research on dark energy and dark matter. The new visualization method allows for the first time to present large simulations of dark matter particles in their velocity space in real-time and shows the results of such a simulation on the largest screen in the world. The presentation will be available to the public starting in 2013.

New Method

A density distribution from a dark matter simulation with about 134 million particles, resulting in about 804 million tetrahedra, respectively 3.2 billion triangles. The mesh is deformed by gravitational forces, causing the tetrahedral cells to warp and overlap. The new visualization method uses full phase-space information to generate a tetrahedral tessellation of the computational domain, with mesh vertices defined by the simulation’s dark matter particle positions. Over time the mesh is deformed by gravitational forces, causing the tetrahedral cells to warp and overlap.

The tracer particle positions are stored in a three-dimensional float volume and processed in the geometry shader. Here the six (deformed) tetrahedra are constructed, based on the current tracer positions, and the mass as well as the volume for each tetrahedron is computed on-the-fly. A cell-projection approach in the fragment shader is used to compute the accumulated projected densities in the image plane.

All connectivity and derived information, like the volumes and mass densities of the tetrahedral cells, are generated on-the-fly on the GPU in OpenGL shaders.

The tracer particle positions are stored in a three-dimensional float-point texture, enabling the access and sampling of the cell vertices in the vertex shader. The instance counter (gl_InstanceID) determines which tetrahedral elements are processed and the particle positions are obtained from the position texture and processed in the geometry shader. Here the six (deformed) tetrahedra are constructed, based on the current tracer positions, and the mass as well as the volume for each tetrahedron is computed on-the-fly. A cell-projection approach in the fragment shader is used to compute the accumulated projected densities in the image plane.
